Abstract

We present a (randomized) test for monotonicity of Boolean functions. Namely, given the ability to query an unknown function $f : \{0,1\}^n \mapsto \{0,1\}$ at arguments of its choice, the test always accepts a monotone f, and rejects f with high probability if it is ϵ-far from being monotone (i.e., every monotone function differs from f on more than an ϵ fraction of the domain). The complexity of the test is $O(n/\epsilon)$.

The analysis of our algorithm relates two natural combinatorial quantities that can be measured with respect to a Boolean function; one being global to the function and the other being local to it. A key ingredient is the use of a *switching* (or *sorting*) operator on functions.

1 Introduction

In this work we address the problem of *testing whether a given Boolean function is monotone*. A function $f : \{0,1\}^n \mapsto \{0,1\}$ is said to be monotone if $f(x) \leq f(y)$ for every $x \prec y$, where $\prec$ denotes the natural partial order among strings (i.e., $x_1 \cdots x_n \prec y_1 \cdots y_n$ if $x_i \leq y_i$ for every i and $x_i < y_i$ for some i). The testing algorithm can request the value of the function on arguments of its choice, and is required to distinguish monotone functions from functions that are far from being monotone.

More precisely, the testing algorithm is given a *distance* parameter $\epsilon > 0$, and oracle access to an unknown function f mapping $\{0,1\}^n$ to $\{0,1\}$. If f is a monotone then the algorithm should accept it with probability at least $2/3$, and if f is at distance greater than ϵ from any monotone function then the algorithm should reject it with probability at least $2/3$. Distance between functions is measured in terms of the fraction of the domain on which the functions differ. The complexity measures we focus on are the *query complexity* and the *running time* of the testing algorithm.

We present a randomized algorithm for testing the monotonicity property whose query complexity and running time are linear in n and $1/\epsilon$. The algorithm performs a simple local test: It verifies whether monotonicity is maintained for randomly chosen pairs of strings that differ exactly on a single bit. In our analysis we relate this local measure to the global measure we are interested in — the minimum distance of the function to any monotone function.

1.1 Perspective

Property Testing, as explicitly defined by Rubinfeld and Sudan [31] and extended in [22], is best known by the special case of *low degree testings*[1] [13, 20, 31, 30, 5] which plays a central role in the construction of probabilistically checkable proofs (PCP) [7, 6, 18, 4, 3, 30, 5]. The recognition that property testing is a general notion has been implicit in the context of PCP: It is understood that low degree tests as used in this context are actually codeword tests (in this case of BCH codes), and that such tests can be defined and performed also for other error-correcting codes such as the Hadamard Code [3, 10, 11, 8, 9, 29, 32], and the "Long Code" [9, 25, 26, 32].

For as much as error-correcting codes emerge naturally in the context of PCP, they do not seem to provide a natural representation of familiar objects whose properties we may wish to investigate. That is, one can certainly encode any given object by an error-correcting code — resulting in a (legitimate yet) probably unnatural representation of the object — and then test properties of the encoded object. However, this can hardly be considered as a "natural test" of a "natural phenomena". For example, one may indeed represent a graph by applying an error correcting code to its adjacency matrix (or to its incidence list), but the resulting string is not the "natural representation" of the graph.

The study of Property Testing as applied to natural representation of (non-algebraic) objects was initiated in [22]. In particular, Property Testing as applied to *graphs* has been studied in [22, 23, 24] – where the first work considers the *adjacency matrix representation* of graphs (most adequate for dense graphs), and the latter works consider the *incidence list representation* (adequate for sparse graphs).

In this work we consider property testing as applied to the most generic (i.e., least structured) object – an arbitrary Boolean function. In this case the choice of representation is "forced" upon us.

[1] That is, testing whether a function (over some finite field) is a polynomial of some bounded degree d, or whether it differs significantly from any such polynomial.

1.2 Monotonicity

In interpreting monotonicity it is useful to view Boolean functions over $\{0,1\}^n$ as subsets of $\{0,1\}^n$, called *concepts*. This view is the one usually taken in the PAC Learning literature. Each position in $\{1,\ldots,n\}$ corresponds to a certain *attribute*, and a string $x = x_1 \cdots x_n \in \{0,1\}^n$ represents an instance where $x_i = 1$ if and only if the instance x has the i^{th} attribute. Thus, a concept (subset of instances) is monotone if the presence of additional attributes maintains membership of instances in the concept (i.e., if instance x is in the concept C then any instance resulting from x by adding some attributes is also in C).

The class of monotone concepts is quite general and rich. On the other hand, monotonicity suggests a certain aspect of simplicity. Namely, each attribute has a uni-directional effect on the value of the function. Thus, knowing that a concept is monotone may be useful in various applications. In fact, this form of simplicity is exploited by Angluin's learning algorithm for monotone concepts [2], which uses membership queries and has complexity that is linear in the number of terms in the DNF representation of the target concept.

We note that an efficient tester for monotonicity is useful as a preliminary stage before employing Angluin's algorithm. As is usually the case, Angluin's algorithm relies on the premise that the unknown target concept is in fact monotone. It is possible to simply apply the learning algorithm without knowing whether the premise holds, and hope that either the algorithm will succeed nonetheless in finding a good hypothesis or detect that the target is not monotone. However, due to the dependence of the complexity of Angluin's algorithm on the number of terms of the target concept's DNF representation, it may be much more efficient to first test whether the function is at all monotone (or close to it).

1.3 The natural monotonicity test

In this paper we show that a tester for monotonicity is obtained by repeating the following $O(n/\epsilon)$ times: Uniformly select a pair of strings at Hamming distance 1 and check if monotonicity is satisfied with respect to the value of f on these two strings. That is,

ALGORITHM 1: On input n, ϵ and oracle access to $f : \{0,1\}^n \mapsto \{0,1\}$, repeat the following steps up to n/ϵ times

1. Uniformly select $x \in \{0,1\}^n$ and $i \in \{1,...,n\}$.
2. Obtain the values of $f(x)$ and $f(y)$, where y results from x by flipping the i^{th} bit.
3. If $x, y, f(x), f(y)$ demonstrate that f is not monotone then reject.

   That is, if either $(x \prec y) \wedge (f(x) > f(y))$ or $(y \prec x) \wedge (f(y) > f(x))$ then reject.

If all iterations were completed without rejecting then accept.

Theorem 1 *Algorithm 1 is a testing algorithm for monotonicity. Furthermore, if the function is monotone then Algorithm 1 always accepts.*

Theorem 1 asserts that a (random) *local check* (i.e., Step 3 above) can establish the existence of a *global property* (i.e., the distance of f to the set of monotone functions). Actually, Theorem 1 is proven by relating two quantities referring to the above: Given $f : \{0,1\}^n \mapsto \{0,1\}$, we denote by $\delta_{\text{M}}(f)$ the fraction of pairs of n-bit strings, differing on one bit, which violate the monotonicity condition (as stated in Step 3). We then define $\epsilon_{\text{M}}(f)$ to be the distance of f from the set of monotone

functions (i.e., the minimum over all monotone functions g of $|\{x : f(x) \neq g(x)\}|/2^n$). Observing that Algorithm 1 always accepts a monotone function, Theorem 1 follows from Theorem 2, stated below.

Theorem 2 *For any $f : \{0,1\}^n \mapsto \{0,1\}$,*

$$\delta_{\mathrm{M}}(f) \;\geq\; \frac{\epsilon_{\mathrm{M}}(f)}{n}.$$

On the other hand,

Proposition 3 *For every function $f : \{0,1\}^n \mapsto \{0,1\}$, $\epsilon_{\mathrm{M}}(f) \geq \delta_{\mathrm{M}}(f)/2$.*

Thus, for every function f

$$\frac{\epsilon_{\mathrm{M}}(f)}{n} \;\leq\; \delta_{\mathrm{M}}(f) \;\leq\; 2 \cdot \epsilon_{\mathrm{M}}(f) \tag{1}$$

A natural question that arises is that of the exact relation between $\delta_{\mathrm{M}}(\cdot)$ and $\epsilon_{\mathrm{M}}(\cdot)$. We observe that this relation is not simple; that is, it does not depend only on the values of δ_{M} and ϵ_{M}. Moreover, we show that both the lower and the upper bound of Equation (1) may be attained (up to a constant factor).

Proposition 4 *For every $c < 1$, there exists $c' < 1$ so that for any sufficiently large n, and for any α such that $2^{-c \cdot n} \leq \alpha \leq \frac{1}{2}$:*

1. *There exists a function $f : \{0,1\}^n \mapsto \{0,1\}$ such that $\alpha \leq \epsilon_{\mathrm{M}}(f) \leq 2\alpha$ and*

$$\delta_{\mathrm{M}}(f) \;=\; \frac{2}{n} \cdot \epsilon_{\mathrm{M}}(f)\,.$$

2. *There exists a function $f : \{0,1\}^n \mapsto \{0,1\}$ such that $(1 - o(1)) \cdot \alpha \leq \epsilon_{\mathrm{M}}(f) \leq 2\alpha$*

$$\delta_{\mathrm{M}}(f) \;=\; (1 \pm o(1)) \cdot (1 - c) \cdot \epsilon_{\mathrm{M}}(f)\,.$$

Perspective. Analogous quantities capturing local and global properties of functions were analyzed in the context of *linearity testing*. For a function $f : \{0,1\}^n \mapsto \{0,1\}$ (as above), one may define $\epsilon_{\mathrm{LIN}}(f)$ to be its distance from the set of linear functions and $\delta_{\mathrm{LIN}}(f)$ to be the fraction of pairs, $(x, y) \in \{0,1\}^n \times \{0,1\}^n$ for which $f(x) + f(y) \neq f(x \oplus y)$. A sequence of works [13, 10, 11, 8] has demonstrated a fairly complex behavior of the relation between δ_{LIN} and ϵ_{LIN}. The interested reader is referred to [8].

Previous Bound on $\delta_{\mathrm{M}}(f)$. This paper is the journal version of [21]. In [21], a weaker version of Theorem 2 was proved. In particular it was shown that $\delta_{\mathrm{M}}(f) \;=\; \Omega\left(\frac{\epsilon_{\mathrm{M}}(f)}{n^2 \log(1/\epsilon_{\mathrm{M}}(f))}\right)$, thus yielding a testing algorithm whose complexity grows quadratically with n instead of linearly (as done here). Furtheremore, the proof was more involved and the techniques did not lend themselves to obtain the results presented subsequently for testing monotonicity over domain alphabets other than $\{0,1\}$.

1.4 Monotonicity testing based on random examples

Algorithm 1 makes essential use of queries. We show that this is no coincidence – any monotonicity tester that utilizes only uniformly and *independently* chosen random examples, must have much higher complexity.

Theorem 5 *For any $\epsilon = O(n^{-3/2})$, any tester for monotonicity that only utilizes random examples must use at least $\Omega(\sqrt{2^n/\epsilon})$ such examples.*

Interestingly, this lower bound is tight (up to a constant factor).

Theorem 6 *There exists a tester for monotonicity which only utilizes random examples and uses at most $O(\sqrt{2^n/\epsilon})$ examples, provided $\epsilon > n^2 \cdot 2^{-n}$. For $\epsilon \leq n^2 \cdot 2^{-n}$, the algorithm uses at most $O(n \cdot \sqrt{2^n/\epsilon})$ examples. Furthermore, the algorithm runs in time $\mathrm{poly}(n) \cdot \sqrt{2^n/\epsilon}$.*

We note that the above tester is significantly faster than any learning algorithm for the class of all monotone concepts when the allowed error is $O(1/\sqrt{n})$: Learning (under the uniform distribution) requires $\Omega(2^n/\sqrt{n})$ examples (and even that number of queries) [27].[2]

1.5 Extensions

1.5.1 Other Domain Alphabets

Let Σ be a finite alphabet, and $<_\Sigma$ a (total) order on Σ. Then we can extend the notion of monotonicity to Boolean functions over Σ^n, in the obvious manner: Namely, a function $f : \Sigma^n \mapsto \{0,1\}$ is said to be monotone if $f(x) \leq f(y)$ for every $x \prec_\Sigma y$, where $x_1 \cdots x_n \prec_\Sigma y_1 \cdots y_n$ if $x_i \leq_\Sigma y_i$ for every i and $x_i <_\Sigma y_i$ for some i.

A straightforward generalization of our algorithm yields a testing algorithm for monotonicity of functions over Σ^n with complexity $O\left(|\Sigma| \cdot \frac{n}{\epsilon}\right)$. By modifying the algorithm we can obtain a dependence on $|\Sigma|$ that is only logarithmic instead of linear. By an alternative modification we can remove the depedence on $|\Sigma|$ completely at the cost of increasing the dependence on n/ϵ from linear to quadratic.

1.5.2 Other Ranges

We may further extend the notion of monotonicity to finite ranges other than $\{0,1\}$: Let Ξ be a finite set and $<_\Xi$ a (total) order on Ξ. We say that a function : $\Sigma^n \mapsto \Xi$ is monotone if $f(x) \leq_\Xi f(y)$ for every $x \prec_\Sigma y$. We show that every algorithm for testing monotonicity of Boolean function that works by observing pairs of strings selected according to some fixed distribution (as our algorithms do), can be transformed to testing monotonicity of functions over any finite range Ξ. The increase in the complexity of the algorithm is by a multiplicative factor of $|\Xi|$. Recently, Doddis, Lehman and Raskhodnikova have devised a transformation whose dependency on the size of the range is only logarithmic [16].

[2] The claim follows by considering all possible concepts that contain all instances having $\lfloor n/2 \rfloor + 1$ or more 1's, no instances having $\lfloor n/2 \rfloor - 1$ or less 1's, and any subset of the instances having exactly $\lfloor n/2 \rfloor$ 1's. In contrast, "weak learning" [28] is possible in polynomial time. Specifically, the class of monotone concepts can be learned in polynomial time with error at most $1/2 - \Omega(1/\sqrt{n})$ (though no polynomial-time learning algorithm can achieve an error of $1/2 - \omega(\log(n)/\sqrt{n})$) [12]).

1.5.3 Testing Unateness.

A function $f : \{0,1\}^n \mapsto \{0,1\}$ is said to be unate if for every $i \in \{1,\ldots,n\}$, exactly one of the following holds: whenever the i^{th} bit is flipped from 0 to 1 then the value of f does not decrease; *or* whenever the i^{th} bit is flipped from 1 to 0 then the value of f does not decrease. Thus, unateness is a more general notion than monotonicity. We show that our algorithm for testing monotonicity of Boolean functions over $\{0,1\}^n$ can be extended to test whether a function is unate or far from any unate function at an additional cost of a (multiplicative) factor of $\sqrt{n}$. The definition of unateness can also be extended to functions over larger domain alphabets and larger ranges, and our algorithms extend to these cases as well.

1.6 Techniques

Our main results are proved using *shifting* of Boolean functions (subsets of $\{0,1\}^n$). Various shifting techniques play an important role in extremal set theory (cf., [19] as well as [1, 15]). A typical application is for showing that a function has a certain property. This is done by shifting the function so that the resulting function is simpler to analyze, whereas shifting *does not introduce* the propetry in question.

Our applications are different. We shift the function to make it monotone, while using a "charging" operator to account for the number of changes made by the shifting process. This "charge" is on one hand related to the distance of the function from being monotone, and on the other hand related to the local check conducted by our testing algorithm.

Actually we will be using several names for the same procedure – *sorting* and *switching* will also make an appearance.

1.7 Related Work

The "spot-checker for sorting" presented in [17, Sec. 2.1] implies a tester for monotonicity with respect to functions from any fully ordered domain to any fully ordered range, having query and time complexities that are logarithmic in the size of the domain. We note that this problem corresponds to the special case of $n = 1$ of the extension discussed in Subsection 1.5 (to general domains and ranges).

1.8 An Open Problem

Our algorithm (even for the case $f : \{0,1\}^n \mapsto \{0,1\}$), has a linear dependence on the dimension of the input, n. As shown in Proposition 4, this dependence on n is unavoidable in the case of our algorithm. However, it is an interesting open problem whether other algorithms may have significantly lower query (and time) complexities, and in particular have query complexity independent of n. A candidate alternative algorithm inspects pairs of strings (x, y), where x is chosen uniformly in $\{0,1\}^n$, and y is chosen as follows: First select an index (*weight*) $w \in \{0,\ldots,n\}$ with probability $\binom{n}{w} \cdot 2^{-n}$, and then select y uniformly among the strings having w 1's, and being comparable to x (i.e., $y \prec x$ or $y \succ x$).

Organization

Theorem 2 is proved in Section 3. Propositions 3 and 4 are proved in Section 4. The extension to domains alphabets and ranges other than $\{0,1\}$, is presented in Section 5, and the extension to

testing Unateness is described in Section 6. Theorems 5 and 6 are proved in Section 7.

2 Preliminaries

For any pair of functions $f, g : \{0,1\}^n \to \{0,1\}$, we define the *distance* between f and g, denoted, $\mathrm{dist}(f,g)$, to be the fraction of instances $x \in \{0,1\}^n$ on which $f(x) \neq g(x)$. In other words, $\mathrm{dist}(f,g)$ is the probability over a uniformly chosen x that f and g differ on x. Thus, $\epsilon_{\mathrm{M}}(f)$ as defined in the introduction is the minimum, taken over all monotone functions g of $\mathrm{dist}(f,g)$.

A general formulation of Property Testing was suggested in [22], but here we consider a special case formulated previously in [31].

Definition 1 (property tester)*: Let* $\mathrm{P} = \cup_{\mathrm{n}\geq 1}\mathrm{P_n}$ *be a subset* (or a property) *of Boolean functions, so that* P_n *is a subset of the functions mapping* $\{0,1\}^n$ *to* $\{0,1\}$*. A* (property) tester for P *is a probabilistic oracle machine*[3]*, M, which given n, a* distance parameter $\epsilon > 0$ *and oracle access to an arbitrary function* $f : \{0,1\}^n \mapsto \{0,1\}$ *satisfies the following two conditions:*

1. The tester accepts f if it is in P :
   If $f \in \mathrm{P}_n$ *then* $\quad \mathrm{Prob}(M^f(n,\epsilon)=1) \geq \frac{2}{3}$.
2. The tester rejects f if it is far from P :
   If $\quad \mathrm{dist}(f,g) > \epsilon$ *for every* $g \in \mathrm{P}_n$, $\quad$ *then* $\quad \mathrm{Prob}(M^f(n,\epsilon)=1) < \frac{1}{3}$.

Testing based on random examples. In case the queries made by the tester are uniformly and *independently* distributed in $\{0,1\}^n$, we say that it only uses examples. Indeed, a more appealing way of looking as such a tester is as an ordinary algorithm (rather than an oracle machine) which is given as input a sequence $(x_1, f(x_1)), (x_2, f(x_2)), ...$ where the x_i's are uniformly and independently distributed in $\{0,1\}^n$.

3 Proof of Theorem 2

In this section we show how every function f can be transformed into a monotone function g. By definition of $\epsilon_{\mathrm{M}}(f)$, the number of modification performed in the transformation must be *at least* $\epsilon_{\mathrm{M}}(f) \cdot 2^n$. On the other hand, we shall be able to *upper bound* the number of modifications by $\delta_{\mathrm{M}}(f) \cdot n \cdot 2^n$, thus obtaining the bound on $\delta_{\mathrm{M}}(f)$ stated in Theorem 2.

For any $i \in \{1,\ldots,n\}$, we say that a function f is *monotone in dimension* i, if for every $\alpha \in \{0,1\}^{i-1}$ and $\beta \in \{0,1\}^{n-i}$, $\; f(\alpha\,0\,\beta) \leq f(\alpha\,1\,\beta)$. For a set of indices $\mathrm{T} \subseteq \{1,\ldots,n\}$, we say that f is *monotone in dimensions* T, if for every $i \in \mathrm{T}$, the function f is monotone in dimension i. We next define a *switch* operator, S_i which transforms any function f to a function $S_i(f)$ that is monotone in dimension i.

Definition 2 *For every* $i \in \{1,\ldots,n\}$*, the function* $S_i(f) : \{0,1\}^n \mapsto \{0,1\}$ *is defined as follows: For every* $\alpha \in \{0,1\}^{i-1}$ *and every* $\beta \in \{0,1\}^{n-i}$*, if* $f(\alpha\,0\,\beta) > f(\alpha\,1\,\beta)$ *then* $S_i(f)(\alpha\,0\,\beta) = f(\alpha\,1\,\beta)$*, and* $S_i(f)(\alpha\,1\,\beta) = f(\alpha\,0\,\beta)$*. Otherwise,* $S_i(f)$ *is defined as equal to* f *on the strings* $\alpha\,0\,\beta$ *and* $\alpha\,1\,\beta$*.*

[3] Alternatively, one may consider a RAM model of computation, in which trivial manipulation of domain and range elements (e.g., reading/writing an element and comparing elements) is performed at unit cost.

Let

$$\mathrm{U} \stackrel{\text{def}}{=} \{(x,y) \ : \ x \text{ and } y \text{ differ on a single bit and } x \prec y\} \tag{2}$$

be the set of *neighboring pairs*, and let

$$\Delta(f) = \{(x,y) \ : \ (x,y) \in \mathrm{U} \text{and } f(x) > f(y)\} \tag{3}$$

be the set of *violating (neighboring) pairs*. Hence, $|\mathrm{U}| = \frac{1}{2} \cdot 2^n \cdot n$, and by definition of $\delta(f)$, we have $\delta(f) = \frac{|\Delta(f)|}{|\mathrm{U}|}$. Let $D_i(f) \stackrel{\text{def}}{=} \{x : S_i(f)(x) \neq f(x)\}$, so that $D_i(f)$ is twice the number of pairs in $\Delta(f)$ that differ on the i^{th} bit (and $\sum_{i=1}^{n} D_i(f) = 2 \cdot |\Delta(f)|$). We show:

Lemma 7 *For every $f : \{0,1\}^n \mapsto \{0,1\}$ and $j \in [n]$, we have:*

1. *If f is monotone in dimensions $\mathrm{T} \subseteq [n]$ then $S_j(f)$ is monotone in dimensions $\mathrm{T} \cup \{j\}$;*
2. *For every $1 \leq i \neq j \leq n$, $D_j(S_i(f)) \leq D_j(f)$.*

We prove the lemma momentarily. First we show how Theorem 2 follows. Let $g = S_n(S_{n-1}(\cdots(S_1(f))\cdots)$. By successive application of the first item of Lemma 7, the function g is monotone, and hence $\mathrm{dist}(f,g) \geq \epsilon_{\mathrm{M}}(f)$. By successive applications of the second item,

$$D_i(S_{i-1}(\cdots(S_1(f))\cdots) \ \leq \ D_i(S_{i-2}(\cdots(S_1(f))\cdots) \ \leq \ \cdots \ \leq \ D_i(f) \tag{4}$$

and so

$$\mathrm{dist}(f,g) \ \leq \ 2^{-n} \cdot \sum_{i=1}^{n} D_i(S_{i-1}(\cdots(S_1(f))\cdots) \ \leq \ 2^{-n} \cdot \sum_{i=1}^{n} D_i(f) \, . \tag{5}$$

Therefore,

$$\sum_{i=1}^{n} D_i(f) \geq \mathrm{dist}(f,g) \cdot 2^n \geq \epsilon_{\mathrm{M}}(f) \cdot 2^n \tag{6}$$

On the other hand, by definition of $D_i(f)$,

$$\sum_{i=1}^{n} D_i(f) \ = \ 2 \cdot |\Delta(f)| \ = \ 2 \cdot \delta_{\mathrm{M}}(f) \cdot |\mathrm{U}| \ = \ \delta_{\mathrm{M}}(f) \cdot 2^n \cdot n \tag{7}$$

where U and $\Delta(f)$ were defined in Equations (2) and (3), respectively. Theorem 2 follows by combining Equations (6) and (7).

Proof of Lemma 7: A key observation is that for every $i \neq j$, the effect of S_j on monotonicity of f in dimension i (resp., the effect of S_i on $D_j(\cdot)$) can be analyzed by considering separately each restriction of f at the other coordinates.

Item 1. Clearly, $S_j(f)$ is monotone in dimension j. We show that $S_j(f)$ is monotone in any dimension $i \in \mathrm{T}$. Fixing any $i \in \mathrm{T}$, and assuming without loss of generality, that $i < j$, we fix any $\alpha \in \{0,1\}^{i-1}$, $\beta \in \{0,1\}^{j-i-1}$ and $\gamma \in \{0,1\}^{n-j}$, and consider the function $f'(\sigma\tau) \stackrel{\text{def}}{=} f(\alpha\,\sigma\,\beta\,\tau\,\gamma)$. Clearly f' is monotone in dimension 1 and we need to show that so is $S_2(f')$. In other words, consider the 2-by-2 zero-one matrix whose (σ,τ)-entry is $f'(\sigma\,\tau)$. Our claim thus amounts to saying that if one sorts the rows of a 2-by-2 matrix which is column-sorted then the columns remain sorted. This is easily verified by a simple case analysis. For a more general argument, concerning any $d \times d$ zero-one matrix, see the proof of Lemma 8.

Item 2. Fixing $i, j, \alpha, \beta, \gamma$ and defining f' as above, here we need to show that $D_2(S_1(f')) \leq D_2(f')$. Again, we consider the 2-by-2 zero-one matrix whose (σ, τ)-entry is $f'(\sigma\,\tau)$. The current claim amounts to saying that for any such matrix if we sort the columns then the number of unsorted rows cannot increase. (Recall that D_2 equals twice the number of unsorted rows.) The claim is easily verified by a simple case analysis. For a more general argument, concerning any $d \times 2$ zero-one matrix, see the proof of Lemma 8. (We note that the claim is false for $d \times d$ zero-one matrices, starting at $d \geq 4$ as well as for 2-by-2 matrices over $\{0, 1, 2\}$.) ■

4 Proofs of Propositions 3 and 4

Below we prove the propositions concerning the other relations between $\epsilon_{\mathrm{M}}(f)$ and $\delta_{\mathrm{M}}(f)$ that were stated in the introduction.

Proof of Propositions 3: Let us fix f and consider the set $\Delta(f)$ of its violating pairs (as defined in Equation (3)). In order to make f monotone, we must modify the value of f on at least one string in each violating pair. Since each string belongs to at most n violating pairs, the number of strings whose value must be modified (i.e., $\epsilon_{\mathrm{M}}(f) \cdot 2^n$) is at least

$$\frac{|\Delta(f)|}{n} = \frac{\delta_{\mathrm{M}}(f) \cdot |\mathrm{U}|}{n} = \frac{\delta_{\mathrm{M}}(f) \cdot \left(\frac{1}{2} \cdot 2^n \cdot n\right)}{n} = \frac{\delta_{\mathrm{M}}(f)}{2} \cdot 2^n$$

(where U is as defined in Equation (2)). and the proposition follows. ■

Comment: For each string z, if $f(z) = 0$ then at most all pairs $(x, z) \in \mathrm{U}$ are violating, and if $f(z) = 1$, then at most all pairs $(z, y) \in \mathrm{U}$ are violating. The number of former pairs equals the number of 1's in z and the number of latter pairs equals the number of 0's in z. Since all but a small fraction of strings have roughly $n/2$ 1's and $n/2$ 0's, the above bound can be improved to yield $\epsilon_{\mathrm{M}} \geq (1 - o(1)) \cdot \delta_{\mathrm{M}}(f)$, provided $\delta_{\mathrm{M}}(f) \geq 2^{-cn}$ for any constant $c < 1$¿

Proof of Proposition 4: It will be convinient to view the Boolean Lattice as a directed layered graph G_n. Namely, each string in $\{0,1\}^n$ corresponds to a vertex in G_n. For every vertex $y = y_1 \ldots y_n$, and for every i such that $y_i = 1$, there is an edge directed from y to $x = y_1 \ldots y_{i-1} 0 y_{i+1} \ldots y_n$. Thus G_n is simply a directed version of the hypercube graph. We refer to all vertices corresponding to strings having exactly i 1's as belonging to the i^{th} *layer* of G_n, denoted L_i. By definition of the edges in the graph, there are only edges between consecutive layers. For any function $f : \{0,1\}^n \mapsto \{0,1\}$, we say that an edge from y to x is *violating* with respect to f, if $f(x) > f(y)$ (which implies that $(x, y) \in \Delta(f)$). The fraction of violating edges (among all $\frac{1}{2} \cdot 2^n \cdot n$ edges), is by definition $\delta_{\mathrm{M}}(f)$.
We start by proving both items for the case where $\alpha = \frac{1}{2} - O(\frac{1}{\sqrt{n}})$.

Item 1. Let $f = g_n$ be defined on $\{0,1\}^n$ in the following way: $g_n(x) = 1$ if $x_1 = 0$, and $g_n(x) = 0$ if $x_1 = 1$ (thus g_n is the "dictatorship" function). By definition of g_n, for every $\beta \in \{0,1\}^{n-1}$, the edge $(1\,\beta, 0\,\beta)$ is a violating edge with respect to g_n, and there are no other violating edges (since for every edge (y, x) such that $x_1 = y_1$, we have $g_n(x) = g_n(y)$.) Since the number of violating edges is 2^{n-1} (as there is a single edge for each $\beta \in \{0,1\}^n$), and the total number of edges is $\frac{1}{2} \cdot 2^n \cdot n$, we have $\delta_{\mathrm{M}}(g_n) = \frac{2^{n-1}}{\frac{1}{2} \cdot 2^n \cdot n} = \frac{1}{n}$

On the other hand, we next show that $\epsilon_{\rm M}(g_n) = \frac{1}{2}$. Clearly, $\epsilon_{\rm M} \leq \frac{1}{2}$ as the all 0 function is monotone and at distance $\frac{1}{2}$ from g_n. It remains to show that we cannot do better. To this end, observe that the violating edges, of which there are 2^{n-1}, define a matching between $\mathrm{C} \stackrel{\rm def}{=} \{y \in \{0,1\}^n \ : \ y_1 = 1\}$ and $\overline{\mathrm{C}} \stackrel{\rm def}{=} \{x \in \{0,1\}^n \ : \ x_1 = 0\}$ (where for every $\beta \in \{0,1\}^{n-1}$, $y = 1\,\beta$ is matched with $x = 0\,\beta$). To make g_n monotone, we must modify the value of g_n on at least one vertex in each matched pair, and since these pairs are disjoint the claim follows.

Item 2. Let $f = h_n : \{0,1\}^n \mapsto \{0,1\}$ be the (symmetric) function that has value 0 on all vertices belonging to layers L_i where i is even, and has value 1 on all vertices belonging to layers L_i where i is odd (i.e., h_n is the parity function). Since all edges going from even layers to odd layers are violating edges, $\delta_{\rm M}(h_n) = 1/2$. We next show that $\epsilon_{\rm M}(h_n) \geq \frac{1}{2} - O(\frac{1}{\sqrt{n}})$ (where once again, $\epsilon_{\rm M}(h_n) \leq \frac{1}{2}$ since it is at distance at most $1/2$ either from the all-0 function or the all-1 function). Consider any pair of adjacent layers such that the top layer is labeled 0 (so that all edges between the two layers are violating edges). It can be shown (*cf.* [14, Chap. 2, Cor. 4]) using Hall's Theorem, that for any such pair of adjacent layers, there exists a perfect matching between the smallest among the two layers and a subset of the larger layer. The number of unmatched vertices is hence $\sum_{i=1}^{\lceil n/2 \rceil} \big|\, |\mathrm{L}_{2i}| - |\mathrm{L}_{2i-1}| \,\big| + 1$ (where $\mathrm{L}_{n+1} \stackrel{\rm def}{=} \emptyset$, and the $+1$ is due to the all 0 string). This sum can be bounded by

$$2 + 2 \cdot \sum_{i=1}^{\lceil n/4 \rceil} \big|\, |\mathrm{L}_{2i}| - |\mathrm{L}_{2i-1}| \,\big| \ = \ 2 + 2 \cdot \sum_{i=1}^{\lceil n/4 \rceil} |\mathrm{L}_{2i}| - |\mathrm{L}_{2i-1}| \ \leq \ 2 + 2 \cdot |\mathrm{L}_{\lceil n/2 \rceil}| \ = \ O(2^n/\sqrt{n})$$

Thus, we have $(1 - o(1)) \cdot 2^{n-1}$ disjoint violating edges. Since we must modify the value of at least one end-point of each violating edge, $\epsilon_{\rm M}(h_n) \in [0.5 - o(1), 0.5]$ and the claim follows.

To generalize the above two constructions for smaller α we do the following. For each value of α we consider a subset $\mathrm{S} \subset \{0,1\}^n$, such that all strings in S have a certain number of leading 0's, and the size of S is roughly $2\alpha \cdot 2^n$. Thus there is a 1-to-1 mapping between S and $\{0,1\}^{n'}$ for a certain n', and S induces a subgraph of G_n that is isomorphic to $\mathrm{G}_{n'}$. For both case we define f on S analogously to the way it was defined above on $\{0,1\}^n$, and let f be 1 everywhere else. We argue that the values of $\epsilon_{\rm M}(f)$ and $\delta_{\rm M}(f)$ are determined by the value of f on S, and adapt the bounds we obtained above. Details follow.

Item 1. Let $n' = n - \lfloor \log(1/(2\alpha)) \rfloor$, and consider the set S of all strings whose first $n - n'$ bits are set to 0 (thus forming a sub-cube of the n-dimensional cube). The size of the set S is at least $2\alpha \cdot 2^n$ and at most $4\alpha \cdot 2^n$. Clearly the subgraph of G_n induced by vertices in S is isomorphic to $\mathrm{G}_{n'}$. For every $x = 0^{n-n'}\gamma \in \mathrm{S}$ (where $\gamma \in \{0,1\}^{n'}$), we let $f(x) = g_{n'}(\gamma)$, (where $g_{n'} : \{0,1\}^{n'} \mapsto \{0,1\}$ is as defined in the special case of Item 1 above), and for every $x \notin \mathrm{S}$, we let $f(x) = 1$. Therefore, for every $x \in \mathrm{S}$ and $y \notin \mathrm{S}$, either $x \prec y$ or x and y are incomprable. This implies that the closest monotone functions differs from f only on S, and all violating edges (with respect to f) are between vertices in S. Therefore, $\epsilon_{\rm M}(f) = \frac{\epsilon_{\rm M}(h_{n'}) \cdot 2^{n'}}{2^n} = \frac{|\mathrm{S}|/2}{2^n}$ (which ranges between α and 2α), and $\delta_{\rm M}(f) = \frac{\delta_{\rm M}(h_{n'}) \cdot 2^{n'} n'/2}{2^n n/2} = \frac{|\mathrm{S}|/2}{2^n \cdot n/2}$. So $\delta_{\rm M}(f) = \frac{2\epsilon_{\rm M}(f)}{n}$, as desired.

Item 2. Here we let $n' = n - \lfloor \log(1/(2\alpha)) \rfloor$, and define S as in Item 1. Thus, $2\alpha \cdot 2^n \leq |\mathrm{S}| \leq 4\alpha \cdot 2^n$. For every $x = 0^{n-n'}\gamma \in \mathrm{S}$ (where $\gamma \in \{0,1\}^{n'}$), we let $f(x) = h_{n'}(\gamma)$, (where $h_{n'} : \{0,1\}^{n'} \mapsto \{0,1\}$ is as defined in Item 2 above), and for every $x \notin \mathrm{S}$, we let $f(x) = 1$. Therefore, $\epsilon_{\rm M}(f) = \frac{\epsilon_{\rm M}(g_{n'}) \cdot 2^{n'}}{2^n} = \frac{(\frac{1}{2} \pm \frac{1}{\sqrt{n'}}) \cdot |\mathrm{S}|}{2^n}$ (which is greater than $(1 - o(1))\alpha \cdot 2^n$ and less than

$2\alpha \cdot 2^n$), and $\delta_{\mathrm{M}}(f) = \frac{\delta_{\mathrm{M}}(g_{n'}) \cdot 2^{n'} n'/2}{2^n n/2} = \frac{|\mathrm{S}| \cdot n'/4}{2^n \cdot n/2}$. We thus have $\delta_{\mathrm{M}}(f) = \frac{(1 \pm o(1)) \cdot n'}{n} \cdot \epsilon_{\mathrm{M}}(f)$. Since $n' > (1-c) \cdot n - 3$, the claim follows. ■

5 Other Domain Alphabets and Ranges

As defined in the introduction, for finite sets Σ and Ξ and orders $<_\Sigma$ and $<_\Xi$ on Σ and Ξ, respectively, we say that a function $f : \Sigma^n \mapsto \Xi$ is monotone if $f(x) \leq_\Xi f(y)$ for every $x \prec_\Sigma y$, where $x_1 \cdots x_n \prec_\Sigma y_1 \cdots y_n$ if $x_i \leq_\Sigma y_i$ for every i and $x_i <_\Sigma y_i$ for some i. In this subsection we discuss how our algorithm generalizes when Σ and Ξ are not necessarily $\{0,1\}$. We first consider the generalization to $|\Sigma| > 2$ while maintaining $\Xi = \{0,1\}$, and later generalize to any Ξ.

5.1 General Domain Alphabets

Let $f : \Sigma^n \mapsto \{0,1\}$, where $|\Sigma| = d$. Without loss of generality, let $\Sigma = \{1, \ldots, d\}$. A straightforward generalization of Algorithm 1 uniformly selects a set of strings, and for each string x selected it uniformly select an index $j \in 1, \ldots, n$, and queries the function f on x and y, where y is obtained from x by either incrementing or decrementing by one unit the value of x_j. However, as we shall see below, the number of strings that should be selected in order to obtain 2/3 success probability, grows linearly with d. Instead, we show how a modification of the above algorithm, in which the distribution on the pairs (x, y) is different from the above, yields an improved performance. Both algorithms are special cases of the following algorithmic schema.

ALGORITHM 2: The algorithm utilizes a distribution $p : \Sigma \times \Sigma \mapsto [0,1]$, and depends on a function t. Without loss of generality, $p(k,\ell) > 0$ implies $k < \ell$. On input n, ϵ and oracle access to $f : \Sigma^n \mapsto \{0,1\}$, repeat the following steps up to $t(n, \epsilon, |\Sigma|)$ times

1. Uniformly select $i \in \{1, ..., n\}$, $\alpha \in \Sigma^{i-1}$, and $\beta \in \Sigma^{n-i}$.
2. Select (k, ℓ) according to the distribution p.
3. If $f(\alpha\, k\, \beta) > f(\alpha\, \ell\, \beta)$ (that is, a violation of monotonicity is detected), then reject.

If all iterations were completed without rejecting then accept.

The above algorithm clearly generalizes the algorithm suggested at the beginning of this section (where $t(n, \epsilon, d) = \Theta(n \cdot d/\epsilon)$ and the distribution p is uniform over $\{(k, k+1) : 1 \leq k < d\}$). However, as we show below, we can select the distribution p so that $t(n, \epsilon, d) = \Theta(\frac{n}{\epsilon} \cdot \log d)$ will do. Yet a third alternative (i.e., letting p be uniform over all pairs (k, ℓ) with $1 \leq k < \ell \leq d$) allows to have $t(n, \epsilon, d) = O(n/\epsilon)^2$.

Clearly, Algorithm 2 always accepts a monotone function (regardless of the distribution p in use). Our analysis thus focuses on the case the function is not monotone.

5.1.1 Reducing the analysis to the case $n = 1$

We reduce the analysis of the performace of the above algorithm to its performance in the case $n = 1$. The key ingrediant in this reduction is a generalization of Lemma 7. As in the binary case, we describe operators by which any Boolean function over Σ^n can be transformed into a monotone function. In particular we generalize the switch operator (which is now a *sort* operator) to deal with the case $d > 2$.

Definition 3 *For every $i \in \{1,\ldots,n\}$, the function $\mathrm{S}_i(f) : \Sigma^n \mapsto \{0,1\}$ is defined as follows: For every $\alpha \in \Sigma^{i-1}$ and every $\beta \in \Sigma^{n-i}$, we let $\mathrm{S}_i(f)(\alpha\,1\,\beta),\ldots,\mathrm{S}_i(f)(\alpha\,d\,\beta)$ be given the values of $f(\alpha\,1\,\beta),\ldots,f(\alpha\,d\,\beta)$, in* sorted *order.*

Clearly, similarly to the binary case, for each i, the function $S_i(f)$ is monotone in dimension $\{i\}$, where the definition of being monotone in a set of dimentions is as in the binary case.[4] The definitions of U and $\Delta(f) \subseteq \mathrm{U}$ of the binary case (cf., Eq. (2) and (3)) may be extended in several different ways. Specifically, for every $i \in [n] \stackrel{\mathrm{def}}{=} \{1,...,n\}$ and every pair $(k,\ell) \in \Sigma^2$ so that $k < \ell$, we let

$$\mathrm{U}_{i,(k,\ell)} \stackrel{\mathrm{def}}{=} \{(\alpha\,k\,\beta\,,\,\alpha\,\ell\,\beta) \,:\, \alpha \in \Sigma^{i-1}\,,\,\beta \in \Sigma^{n-i}\} \tag{8}$$

$$\Delta_{i,(k,\ell)}(f) \stackrel{\mathrm{def}}{=} \{(x,y) \in \mathrm{U}_{i,(k,\ell)} \,:\, f(x) > f(y)\} \tag{9}$$

In the binary case, $\mathrm{U} = \cup_{i=1}^{n}\mathrm{U}_{i,(1,2)}$ and $\Delta(f) = \cup_{i=1}^{n}\Delta_{i,(1,2)}(f)$. Furthermore, $D_i(f)$ as defined in the binary case, equals twice $|\Delta_{i,(1,2)}(f)|$.

Lemma 8 (Lemma 7 generalized): *For every $f : \Sigma^n \mapsto \{0,1\}$ and $j \in [n]$, we have:*

1. *If f is monotone in dimensions $\mathrm{T} \subseteq [n]$ then $S_j(f)$ is monotone in dimensions $\mathrm{T} \cup \{j\}$;*
2. *For every $i \in [n] \setminus \{j\}$, and for every $1 \leq k < \ell \leq d$*

$$|\Delta_{i,(k,\ell)}(S_i(f))| \;\leq\; |\Delta_{i,(k,\ell)}(f)|$$

Proof: As in the proof of Lemma 7, we may consider the function f restricted at all dimensions but the two in question. Again, the proof of the two items boil down to corresponding claims about sorting matrices.

Item 1. Let i be some index in T, and assume without loss of generality that $i < j$. Again, we fix any $\alpha \in \Sigma^{i-1}$, $\beta \in \Sigma^{j-i-1}$ and $\gamma \in \Sigma^{n-j}$, and consider the function $f' : \Sigma^2 \mapsto \{0,1\}$ defined by $f'(\sigma\tau) \stackrel{\mathrm{def}}{=} f(\alpha\,\sigma\,\beta\,\tau\,\gamma)$. Again, f' is monotone in dimension 1 and we need to show that so is $S_2(f')$ (as it is obvious that $S_2(f')$ is monotone in dimension 2). Our claim thus amounts to saying that if one sorts the rows of a d-by-d matrix which is column-sorted then the columns remain sorted (the matrix we consider has its (σ,τ)-entry equal to $f'(\sigma\,\tau)$).

Let M denote a (d-by-d zero-one) matrix in which each column is sorted. We observe that the number of 1's in the rows of M is monotonicllly non-decreasing (as each column contributes a unit to the 1-count of row k only if it contributes a unit to the 1-count of row $k+1$). That is, if we let o_k denote the number of 1's in the k^{th} row then $o_k \leq o_{k+1}$ for $k = 1,...,d-1$. Now suppose we sort each row of M resulting in a matrix M'. Then the k^{th} row of M' is $0^{d-o_k}1^{o_k}$, and it follows that the columns of M' remain sorted (as the $k+1^{\mathrm{st}}$ row of M' is $0^{d-o_{k+1}}1^{o_{k+1}}$ and $o_k \leq o_{k+1}$).

Item 2. Fixing i,j,α,β,γ and defining f' as above, here we need to show that $|\Delta_{2,(k,\ell)}(S_1(f'))| \leq |\Delta_{2,(k,\ell)}(f')|$. The current claim amounts to saying that for any $d \times 2$ zero-one matrix if we sort the columns then the number of unsorted rows cannot increase. Note that the claim refers only to columns k and ℓ in the d-by-d matrix considred in Item 1, and that $\Delta_{2,(k,\ell)}$ is the set of unsorted rows.

[4] That is, for $\mathrm{T} \subseteq \{1,\ldots,n\}$, we say that the function $f : \Sigma^n \mapsto \{0,1\}$ is *monotone in dimensions* T if for every $i \in \mathrm{T}$, every $\alpha \in \{0,1\}^{i-1}, \beta \in \{0,1\}^{n-i}$, and every $k = 1,...,d-1$, it holds that $f(\alpha\,k\,\beta) \leq f(\alpha\,k+1\,\beta)$.

Let Q denote a (d-by-2 zero-one) matrix in which each column is sorted. Let o_1 (resp., o_2) denote the number of ones in the first (resp., second) column of Q. Then, the number of unsorted rows in Q is $r(Q) \stackrel{\text{def}}{=} o_1 - o_2$ if $o_1 > o_2$ and $r(Q) \stackrel{\text{def}}{=} 0$ otherwise. Let Q' be any matrix with o_1 (resp., o_2) 1's in its first (resp., second) column. Then we claim that the number of unsorted rows in Q' is at least $r(Q)$. The claim is obvious in case $r(Q) = 0$. In case $r(Q) > 1$ we consider the location of the o_1 1's in the first column of Q'. At most o_2 of the corresponding rows in Q' may have a 1-entry also in the second column (as the total of 1's in the second column is o_2), and so the remaining rows (which are at least $o_1 - o_2$ in number) are unsorted. ■

With Lemma 8 at our disposal, we are ready to state and prove that the analysis of Algorithm 2 (for any n) reduces to its analysis in the special case $n = 1$.

Lemma 9 *Let A denote a single iteration of Algorithm 2, and $f : \Sigma^n \mapsto \{0,1\}$. Then there exists functions $f_{i,\alpha,\beta} : \Sigma \mapsto \{0,1\}$, for $i \in [n]$, $\alpha \in \{0,1\}^{i-1}$ and $\beta \in \{0,1\}^{n-i}$, so that the following holds*

1. *$\epsilon_{\mathrm{M}}(f) \leq 2 \cdot \sum_i \mathrm{Exp}_{\alpha,\beta}(\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta}))$, where the expectation is taken uniformly over $\alpha \in \{0,1\}^{i-1}$ and $\beta \in \{0,1\}^{n-i}$.*
2. *The probability that A rejects f is lower bounded by the expected value of $\mathrm{Prob}[A \text{ rejects } f_{i,\alpha,\beta}]$, where the expectation is taken uniformly over $i \in [n]$, $\alpha \in \{0,1\}^{i-1}$ and $\beta \in \{0,1\}^{n-i}$.*

In fact, Theorem 1 follows easily from the above lemma, since in the binary case Algorithm 2 collapses to Algorithm 1 (as there is only one possible distribution p – the one assigning all weight to the single admissible pair $(1,2)$). Also, in the binary case, for any $f' : \{0,1\} \mapsto \{0,1\}$, algorithm A rejects with probability exactly $2\epsilon_{\mathrm{M}}(f')$. Thus, the lemma implies that in the binary case, for any $f : \{0,1\}^n \mapsto \{0,1\}$, algorithm A rejects with probability at least

$$\begin{aligned} \mathrm{Exp}_{i,\alpha,\beta}(\mathrm{Prob}[A \text{ rejects } f_{i,\alpha,\beta}]) &= \mathrm{Exp}_{i,\alpha,\beta}(2\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta})) \\ &\geq \frac{1}{n} \cdot \epsilon_{\mathrm{M}}(f) \end{aligned}$$

The application of the above lemma in the non-binary case is less straightforward (as there the probability that A rejects $f' : \Sigma \mapsto \{0,1\}$ is not necessarily $2\epsilon_{\mathrm{M}}(f')$). Furthermore, algorithm A may be one of infinitely many possibilities, depending on the infinitely many possible distributions p. But let us first prove the lemma.

Proof: For $i = 1, ..., n+1$, we define $f_i \stackrel{\text{def}}{=} \mathrm{S}_{i-1} \cdots \mathrm{S}_1(f)$. Thus, $f_1 \equiv f$, and by Item 1 of Lemma 8, we have that f_{n+1} is monotone. It follows that

$$\epsilon_{\mathrm{M}}(f) \;\leq\; \mathrm{dist}(f, f_{n+1}) \;\leq\; \sum_{i=1}^{n} \mathrm{dist}(f_i, f_{i+1}) \tag{10}$$

Next, for $i = 1, ..., n$, $\alpha \in \{0,1\}^{i-1}$ and $\beta \in \{0,1\}^{n-i}$, define the function $f_{i,\alpha,\beta} : \Sigma \mapsto \{0,1\}$, by $f_{i,\alpha,\beta}(x) = f(\alpha\, x\, \beta)$, for $x \in \Sigma$. Throughout the proof, $\sum_{\alpha,\beta}$ refers to summing over all (α,β)'s in $\Sigma^{i-1} \times \Sigma^{n-i}$, and $\mathrm{Exp}_{\alpha,\beta}$ refers to expectation over uniformly distributed $(\alpha,\beta) \in \Sigma^{i-1} \times \Sigma^{n-i}$. We claim that

$$\mathrm{dist}(f_i, f_{i+1}) \;\leq\; 2 \cdot \mathrm{Exp}_{\alpha,\beta}(\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta})) \tag{11}$$

This inequality is proven (below) by observing that f_{i+1} is obtained from f_i by sorting, seperately, the elements in each $f_{i,\alpha,\beta}$. (The factor of 2 is due to the relationship beween the distance of a

vector to its sorted form and its distnace to monotone.) Thus,

$$\begin{aligned} d^n \cdot \mathrm{dist}(f_i, f_{i+1}) &= \sum_{\alpha,\beta} |\{x \in \Sigma : f_i(\alpha\, x\, \beta) \neq f_{i+1}(\alpha\, x\, \beta)\}| \\ &= \sum_{\alpha,\beta} |\{x \in \Sigma : f_{i,\alpha,\beta}(x) \neq \mathrm{S}_i(f_{i,\alpha,\beta})(x)\}| \\ &\leq \sum_{\alpha,\beta} 2d \cdot \epsilon_{\mathrm{M}}(f_{i,\alpha,\beta}) \end{aligned}$$

where the inequality is justified as follows. Consider a vector $v \in \{0,1\}^d$, and let $\mathrm{S}(v)$ denote its sorted version. Then $\mathrm{S}(v) = 0^z 1^{d-z}$, where z denotes the number of zeros in v. Thus, for some $e \geq 0$, the vector v has e 1-entries within its z-prefix and e 0-entries in its $(d-z)$-suffix. So the number of locations on which v and $\mathrm{S}(v)$ disagree is exactly $2e$. On the other hand, consider an arbitrary perfect matching of the e 1-entries in the prefix and the e 0-entries in the suffice. To make v monotone one must alter at least one entry in each matched pair; thus, $\epsilon_{\mathrm{M}}(v) \geq e/d$.

Combining Eq. (10) and (11), the first item of the lemma follows. In order to prove the second item, we use the definition of algorithm A and let $\chi(E) = 1$ if E holds and $\chi(E) = 0$ otherwise.

$$\begin{aligned} \mathrm{Prob}[A \text{ rejects } f] &= \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{\alpha\,,\,\beta} \mathrm{Prob}_{(k,\ell)\sim p}[f(\alpha\, k\, \beta) > f(\alpha\, \ell\, \beta)] \\ &= \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{(k,\ell)} p(k,\ell) \cdot \sum_{\alpha\,,\,\beta} \chi[f(\alpha\, k\, \beta) > f(\alpha\, \ell\, \beta)] \\ &= \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{(k,\ell)} p(k,\ell) \cdot |\Delta_{i,(k,\ell)}(f)| \end{aligned}$$

Using Item 2 of Lemma 8, we have

$$\begin{aligned} |\Delta_{i,(k,\ell)}(f)| &\geq |\Delta_{i,(k,\ell)}(\mathrm{S}_{i-1}(f))| \\ &\cdots \\ &\geq |\Delta_{i,(k,\ell)}(\mathrm{S}_{i-1} \cdots \mathrm{S}_1(f))| \end{aligned}$$

Combining the above with the definition of f_i, we have

$$\begin{aligned} \mathrm{Prob}[A \text{ rejects } f] &\geq \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{(k,\ell)} p(k,\ell) \cdot \sum_{\alpha\,,\,\beta} \chi[f_i(\alpha\, k\, \beta) > f_i(\alpha\, \ell\, \beta)] \\ &= \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{\alpha\,,\,\beta} \sum_{(k,\ell)} p(k,\ell) \cdot \chi[f_{i,\alpha,\beta}(k) > f_{i,\alpha,\beta}(\ell)] \\ &= \frac{1}{n \cdot d^{n-1}} \sum_{i=1}^{n} \sum_{\alpha\,,\,\beta} \mathrm{Prob}[A \text{ rejects } f_{i,\alpha,\beta}] \end{aligned}$$

and the lemma follows. ■

5.1.2 Algorithms for the case $n = 1$

By the above reduction (i.e., Lemma 9), we may focus on designing algorithms for the case $n = 1$. The design of such algorithms amounts to the design of a probability distribution $p : \Sigma^2 \mapsto [0,1]$

(with support only on pairs (k,ℓ) with $k < \ell$), and the specification of the number of times that the basic iteration of Algorithm 2 is performed. We present three such algorithms, and analyze the performance of a single iteration in them.

ALGORITHM 2.1: This algorithm uses the uniform distribution over pairs $(k, k+1)$, and $t(n,\epsilon,d) = O(nd/\epsilon)$. That is, it uses the distribution $p_1 : \Sigma \times \Sigma \mapsto [0,1]$ defined by $p_1(k,k+1) = 1/(d-1)$ for $k = 1, ..., d-1$.

Proposition 10 *Let A_1 denote a single iteration of Algorithm 2.1, and $f' : \Sigma \mapsto \{0,1\}$. Then, the probability that A_1 rejects f' is at least $\frac{2}{d-1} \cdot \epsilon_{\mathrm{M}}(f')$.*

The lower bound can be shown to be tight (by considering the function f' defined by $f'(x) = 1$ if $x < d/2$ and $f(x) = 0$ otherwise).

Proof: If $\epsilon_{\mathrm{M}}(f') > 0$ then there exists a $k \in \{1, ..., d-1\}$ so that $f'(k) = 1$ and $f(k+1) = 0$. In such a case A_1 rejects with probability at least $1/(d-1)$. On the other hand, $\epsilon_{\mathrm{M}}(f') \leq 1/2$, for every $f' : \Sigma \mapsto \{0,1\}$ (by considering the distance to either the all-zero or the all-one function). ■

ALGORITHM 2.2: This algorithm uses a distribution $p_2 : \Sigma \times \Sigma \mapsto [0,1]$ which is uniform on a set P to be defined below, and $t(n,\epsilon,d) = O((n \log d)/\epsilon)$. The set P consists of pairs (k,ℓ), where $0 < \ell - k \leq 2^t$ and 2^t is the largest power of 2 which divides either k or ℓ. That is, let $\mathrm{power}_2(i) \in \{0, 1..., \log_2 i\}$ denote the largest power of 2 which divides i. Then,

$$P \stackrel{\mathrm{def}}{=} \{(k,\ell) \in \Sigma \times \Sigma : 0 < \ell - k \leq 2^{\max(\mathrm{power}_2(k), \mathrm{power}_2(\ell))}\} \tag{12}$$

We mention that an algorithm of similar performance was presented and analyzed in [17, Sec. 2.1]. Loosely speaking, their algorithm selects a pair (k,ℓ) by first picking k uniformly in $\{1, ..., d-1\}$, next selects t uniformly in $\{0, 1, ..., \log_2(d-k)\}$, and finally selects ℓ uniformly in $\{k+1, ..., k+2^t\} \cap \Sigma$.

Proposition 11 *Let A_2 denote a single iteration of Algorithm 2.2, and $f' : \Sigma \mapsto \{0,1\}$. Then, the probability that A_2 rejects f' is at least $\frac{1}{O(\log d)} \cdot \epsilon_{\mathrm{M}}(f')$.*

Proof: We first show that $|P| = O(d \log d)$. This can be shown by charging each pair $(k,\ell) \in P$ to the element divisible by the larger power of 2 (i.e., to k if $\mathrm{power}_2(k) > \mathrm{power}_2(\ell)$ and to ℓ otherwise), and noting that the charge incurred on each i is at most $2 \cdot 2^{\mathrm{power}_2(i)}$. It follows that the total charge is at most $\sum_{i=1}^{d} 2^{\mathrm{power}_2(i)+1} = \sum_{j=0}^{\log_2 d} \frac{d}{2^j} \cdot 2^{j+1} = O(d \log d)$.

We say that a pair $(k,\ell) \in P$ (where $k < \ell$) is a *violating pair* (with respect to f'), if $f'(k) > f'(\ell)$. By definition, the probability that A_2 rejects f' is the ratio between the number of violating pairs in P (with respect to f'), and the size of P. Thus, it remains to show that the former is $\Omega(\epsilon_{\mathrm{M}}(f) \cdot d)$.

In the following argument it will be convenient to view the indices $1, \ldots, d$ as vertices of a graph and the pairs in P as edges. Specifically, each pair (k,ℓ), where $k < \ell$ corresponds to a *directed* edge from k to ℓ. We refer to this graph as G_P.

Claim 11.1: For every two vertices k and ℓ in G_P, if $k < \ell$ then there is a directed path of length at most 2 from k to ℓ in G_P.

Proof of Claim: Let $r = \lceil \log d \rceil$, and consider the binary strings of length r representing k and ℓ. Let $k = (x_{r-1}, \ldots, x_0)$ and $\ell = (y_{r-1}, \ldots, y_0)$. Let t be the highest index such that $x_t = 0$ and

$y_t = 1$. Note that $x_i = y_i$ for $t < i < r$. We claim that the vertex $m = (x_{r-1}, \ldots, x_{t+1}, 1, 0, \ldots 0)$ is on a path of length 2 from k to ℓ. This follows from the definition of P, since m is divided by 2^t, while both $m - k = 2^t - \sum_{i=0}^{t-1} x_i 2^i \leq 2^t$ and $\ell - m = \sum_{i=0}^{t-1} y_i 2^i < 2^t$. $\square$

We now use the claim to provide a lower bound on the number of violating pairs. Let $z = |\{k : f'(k) = 0\}|$. Then, the number of 1's in the z-prefix of f' must equal the number of 0's in the $(d-z)$-suffice. Let us denote this number by a, and by definition of $\epsilon_{\mathrm{M}}(f')$ we have $\epsilon_{\mathrm{M}}(f') \leq 2a/d$. Consider a matching of the a 1's in the z-prefix to the a 0's in the $(d-z)$-suffice of f'. By the above claim, there is path of length at most 2 in G_P between every matched pair. Clearly, these paths (being of length 2) are edge-disjoint. Since each path starts at a vertex of value 1 and ends at a vertex of value 0, it must contain an edge the corresponds to a violating pair. Thus, we obtain $a \geq \epsilon_{\mathrm{M}}(f')d/2$ violating pairs, and the proposition follows. $\blacksquare$

Algorithm 2.3: This algorithm uses the uniform distribution over all admissible pairs, and $t(n, \epsilon, d) = \min\{O(nd/\epsilon), O(n/\epsilon)^2\}$. That is, it uses the distribution $p_3 : \Sigma \times \Sigma \mapsto [0,1]$ defined by $p_3(k, \ell) = 2/((d-1)d)$ for $1 \leq k < \ell \leq d$.

Proposition 12 *Let A_3 denote a single iteration of Algorithm 2.3, and $f' : \Sigma \mapsto \{0,1\}$. Then, the probability that A_3 rejects f' is at least $\epsilon_{\mathrm{M}}(f')^2/2$.*

The lower bound is tight upto a constant factor: For any integer $e < d/2$, consider the function $f'(x) = 0$ if $x \in \{e+1, ..., 2e\}$ and $f'(x) = 1$ otherwise (then $\epsilon_{\mathrm{M}}(f') = e/d$ and A_3 rejects f' iff it selects a pair in $\{1, ..., e\} \times \{e+1, ..., 2e\}$, which happens with probability $e^2/((d-1)d/2) \approx 2\epsilon_{\mathrm{M}}(f')^2$). On the other hand, note that if $\epsilon_{\mathrm{M}}(f') > 0$ then $\epsilon_{\mathrm{M}}(f') \geq 1/d$ and so the detection probability is at least $\epsilon_{\mathrm{M}}(f')/2d$. This bound is also tight upto a constant factor (e.g., consider $f'(x) = 0$ if $x = 2$ and $f(x) = 1$ otherwise, then $\epsilon_{\mathrm{M}}(f') = 1/d$ and A_3 rejects f' iff it selects the pair $(1, 2)$).

Proof: As in the proof of Lemma 8, let z be the number of zero's in f' and let $2e$ be the number of mismatches between f' and its sorted form. Then $\epsilon_{\mathrm{M}}(f') \leq 2e/d$. On the other hand, considering the e 1-entries in the z-prefix of f' and the e 0-entries in the $(d-z)$-suffix, we lower bound the rejection probability by $e^2/((d-1)d/2) > 2(e/d)^2$. Combining the two, we conclude that A_3 rejects f' with probability at least $2 \cdot (\epsilon_{\mathrm{M}}(f')/2)^2$. $\blacksquare$

On the semi-optimality of Algorithm 2. We call an algorithm, within the framework of Algorithm 2, *smooth* if the number of repetitions (i.e., $t(n, d, \epsilon)$) is linear in ϵ^{-1}. Note that Algorithm 2.2 is smooth, whereas Algorithm 2.3 is not. We claim that Algorithm 2.2 is optimal in its dependence on d, among all smooth algorithms. The following argument is due to Michael Krivilevich.

Proposition 13 *For any distribution $p : \Sigma \times \Sigma \mapsto [0,1]$, with support only on pairs (k, ℓ) such that $k < \ell$, there exists a non-monotone $f' : \Sigma \mapsto \{0,1\}$ so that*

$$\mathrm{Prob}_{(k,\ell)\sim p}[f'(k) > f'(\ell)] \;\leq\; \frac{2}{\log_2 d} \cdot \epsilon_{\mathrm{M}}(f')$$

Proof: Let p be a distribution on pairs as above. We define

$$\rho \stackrel{\mathrm{def}}{=} \max_{f':\Sigma\mapsto\{0,1\} \text{ s.t. } \epsilon_{\mathrm{M}}(f')>0} \left\{ \frac{\mathrm{Prob}_{(k,\ell)\sim p}[f'(k) > f'(\ell)]}{\epsilon_{\mathrm{M}}(f')} \right\}$$

Our aim is to show that $\rho \leq 2/\log_2 d$. The key observation is that for any consecutive $2a$ indices, p has to assign a probability mass of at least $\rho \cdot a/d$ to pairs (k,ℓ) where k is among the lowest a indices and ℓ among the higher a such indices. This observation is proven as follows. Let L, H be the low and high parts of the interval in question; that is, $L = \{s+1, ..., s+a\}$ and $H = \{s+a+1, ..., s+2s\}$, for some $s \in \{0, ..., d-2a\}$. Consider the function f' defined by $f'(i) = 1$ if $i \in L \cup \{s+2a+1, ..., d\}$ and $f'(i) = 0$ otherwise. Then $\epsilon_{\mathrm{M}}(f') = a/d$. On the other hand, the only pairs (k,ℓ) with $f'(k) > f'(\ell)$, are those satisfying $k \in L$ and $\ell \in H$. Thus, by definition of ρ, it must hold that $\rho \leq \Pr_{(k,\ell)\sim p}[k \in L \ \& \ \ell \in H]/(a/d)$, and the observation follows.

The rest of the argument is quite straightforward: Consider $\log_2 d$ partitions of the interval $[1,d]$, so that the i^{th} partition is into consecutive segments of length 2^i. For each segment in the i^{th} partition, probability p assign a probability mass of at least $2^{i-1}\rho/d$ to pairs where one element is in the low part of the segment and the other element is in the high part. Since these segments are disjoint and their number is $d/2^i$, it follows that p assigns a probability mass of at least $\rho/2$ to pairs among halfs of segments in the i^{th} partition. These pairs are disjoint from pairs considered in the other partitions and so we conclude that $(\log_2 d) \cdot \frac{\rho}{2} \leq 1$. The proposition follows. ■

5.1.3 Conclusions for general n

Combining Lemma 9 with Propositions 11 and 12, we obtain.

Theorem 14 *Algorithm 2.2 and Algorithm 2.3 constitute testers of monotonicity for mappings* $\Sigma^n \mapsto \{0,1\}$.

- *The query complexity of Algorithm 2.2 is* $O((n \log d)/\epsilon)$.
- *The query complexity of Algorithm 2.3 is* $O(n/\epsilon)^2$.

Both algorithms run in time $O(q(n,d,\epsilon) \cdot n \log d)$, *where* $q(n,d,\epsilon)$ *is their query complexity.*

Proof: Both algorithms always accept monotone functions, and have complexities as stated. For $a = 2, 3$, let $\delta_a(f)$ denote the rejection probability of a single iteration of Algorithm 2.a when given access to a function $f : \Sigma^n \mapsto \{0,1\}$. Combining Lemma 9 and Proposition 11, we have

$$\begin{array}{rcll} \delta_2(f) & \geq & \mathrm{Exp}_{i,\alpha,\beta}(\delta_2(f_{i,\alpha,\beta})) & \text{[By Part 2 of the lemma]} \\ & \geq & \mathrm{Exp}_{i,\alpha,\beta}(\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta})/O(\log d)) & \text{[By the proposition]} \\ & \geq & \frac{\epsilon_{\mathrm{M}}(f)/O(\log d)}{2n} & \text{[By Part 1 of the lemma]} \end{array}$$

which establishes the claim for Algorithm 2.2. Combining Lemma 9 and Proposition 11, we have

$$\begin{array}{rcll} \delta_3(f) & \geq & \mathrm{Exp}_{i,\alpha,\beta}(\delta_3(f_{i,\alpha,\beta})) & \text{[By Part 2 of the lemma]} \\ & \geq & \mathrm{Exp}_{i,\alpha,\beta}(\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta})^2/2) & \text{[By the proposition]} \\ \text{where} & & \mathrm{Exp}_{i,\alpha,\beta}(\epsilon_{\mathrm{M}}(f_{i,\alpha,\beta})) \ \geq \ \epsilon_{\mathrm{M}}(f)/2n & \text{[By Part 1 of the lemma]} \end{array}$$

So $\delta_3(f)$ is lower bounded by the minimum of $\frac{1}{N} \cdot \sum_{j=1}^{N} x_j^2$ subject to $\frac{1}{N} \cdot \sum_{j=1}^{N} x_j \geq \epsilon_{\mathrm{M}}(f)/2n$, where all x_j's are non-negative. The minimum is obtained when all x_j's are equal, and this establishes the claim for Algorithm 2.3. ■

5.2 General Ranges

Suppose we have an algorithm for testing monotonicity of functions $f : \Sigma^n \mapsto \{0,1\}$ (where Σ is not necessarily $\{0,1\}$). Further assume (as is the case for all algorithms presented here), that the algorithm works by selecting *pairs* of strings according to a particular distribution on pairs, and verifying that monotonicity is not violated on these pairs. We show how to extend such algorithms to functions $f : \Sigma^n \mapsto \Xi$ while losing a factor of $|\Xi|$.

Without loss of generality, let $\Xi = \{0, \ldots, b\}$. The definition of ϵ_{M} extends in the natural way to functions $f : \Sigma^n \mapsto \{0, 1, ..., b\}$. Given a function $f : \Sigma^n \mapsto \{0, 1, ..., b\}$, we define Boolean functions $f_i : \Sigma^n \mapsto \{0,1\}$, by letting $f_i(x) \stackrel{\mathrm{def}}{=} 1$ if $f(x) \geq i$ and $f_i(x) \stackrel{\mathrm{def}}{=} 0$ otherwise, for $i = 1, ..., b$. For any algorithm A that tests monotonicity of Boolean functions as restricted above, and for any Boolean function f, let $\delta^A_{\mathrm{M}}(f)$ be the probability that the algorithm observes a violation when selecting a single pair according to the distribution on pairs it defines. For $f : \Sigma^n \mapsto \{0, 1, ..., b\}$, let $\delta^A_{\mathrm{M}}(f)$ be defined analogously.

Lemma 15 *Let $f : \Sigma^n \mapsto \{0, ..., b\}$, and let f_i's be as defined above.*

1. $\epsilon_{\mathrm{M}}(f) \leq \sum_{i=1}^{b} \epsilon_{\mathrm{M}}(f_i)$.
2. $\delta^A_{\mathrm{M}}(f) \geq \delta^A_{\mathrm{M}}(f_i)$, *for every* i.

Combining the two items and using the relationship between δ^A_{M} and ϵ_{M} in the binary case (i.e., say, $\delta^A_{\mathrm{M}}(f_i) \geq \epsilon_{\mathrm{M}}(f_i)/F$, where F depends on $|\Sigma|$ and n), we get

$$\delta^A_{\mathrm{M}}(f) \;\geq\; \max_i\{\delta^A_{\mathrm{M}}(f_i)\} \;\geq\; \frac{1}{b}\sum_{i=1}^{b}\delta^A_{\mathrm{M}}(f_i) \;\geq\; \frac{1}{b}\sum_{i=1}^{b}\frac{\epsilon_{\mathrm{M}}(f_i)}{F} \;\geq\; \frac{1}{b}\cdot\frac{\epsilon_{\mathrm{M}}(f)}{F}$$

Hence, we may apply algorithm A (designed to test monotonicity of Boolean functions over general domain alphabets), to test monotonicy of functions to arbitrary range of size $b+1$; we only need to increase the number of pairs that A selects by a multiplicative factor of b.

Proof: To prove Item 2, fix any i and consider the set of violating pairs with respect to f_i. Clearly each such pair is also a violating pair with respect to f (i.e., if $x \prec y$ and $f_i(x) > f_i(y)$ then $f_i(x) = 1$ whereas $f_i(y) = 0$, and so $f(x) \geq i > f(y)$). Thus, any pair (x, y) that contributes to $\delta^A_{\mathrm{M}}(f_i)$ also contributes to $\delta^A_{\mathrm{M}}(f)$.

To prove Item 1, consider the Boolean monotone functions closest to the f_i's. That is, for each i, let g_i be a Boolean monotone function closest to f_i. Also, let g_0 be the constant all-one function. Now, define $g : \Sigma^n \mapsto \{0, 1, ..., b\}$ so that $g(x) \stackrel{\mathrm{def}}{=} i$ if i is the largest integer in $\{0, 1, ..., b\}$ so that $g_i(x) = 1$ (such i always exists as $g_0(x) = 1$).

First note that the distance of g from f is at most the sum of the distances of the g_i's from the corresponding f_i's. This is the case since if $g(x) \neq f(x)$ then there must exists an $i \in \{1, ..., b\}$ so that $g_i(x) \neq f_i(x)$ (since if $g_i(x) = f_i(x)$ for all i's then $g(x) = f(x)$ follows).

Finally, we show that g is monotone (and so $\epsilon_{\mathrm{M}}(f) \leq \sum_{i=1}^{b} \epsilon_{\mathrm{M}}(f_i)$ follows). Suppose towards the contradiction that $g(x) > g(y)$ for some $x \prec y$. Let $i \stackrel{\mathrm{def}}{=} g(x)$ and $j \stackrel{\mathrm{def}}{=} g(y) < i$. Then by definition of g, we have $g_i(x) = 1$ and $g_i(y) = 0$, which contradicts the monotonicity of g_i. ■

6 Testing whether a function is Unate

By our definition of monotonicity, a function f is monotone if, for any string, increasing any of its coordinates does not decrease the value of the function. A more general notion is that of *unate* functions. For sake of brevity we focus on Boolean functions over $\{0,1\}^n$, and discuss other finite domain alphabets and ranges at the end of this section. A function $f : \{0,1\}^n \mapsto \{0,1\}$ is *unate* if there exists a sequence $\overline{\pi} = \pi_1 \ldots \pi_n$ where each π_i is one of the two *permutation* over $\{0,1\}$, for which the following holds: For any two strings $x = x_1 \cdots x_n$, and $y = y_1 \cdots y_n$, if for every i we have $x_i \leq_{\pi_i} y_i$, then $f(x) \leq f(y)$, where $<_{\pi_i}$ denotes the total order induced by π_i on Σ (namely, $b \leq_{\pi_i} b'$ if and only if $\pi_i(b) \leq \pi_i(b')$). We say in such a case the f is *monotone with respect to* $\overline{\pi}$.

In particular, if a function is monotone with respect to the sequence $\mathrm{id}, \ldots, \mathrm{id}$, where id is the identity permutation (which induces the order $0 < 1$), then we simply say that it is a monotone function, and if a function is monotone with respect to *some* $\overline{\pi}$, then it is unate.

Similarly to the algorithms presented for testing monotonicity, which search for evidence to non-monotonicity, the testing algorithm for unateness tries to find evidence to non-unateness. However, here it does not suffice to find a pair of strings x, y that differ on the i^{th} bit such that $x \prec y$ while $f(x) > f(y)$. Instead we check whether for some index i and for *each of the two permutations* π, there is a pair of strings, (x, y) that differ only the i^{th} bit, such that $x_i <_\pi y_i$, while $f(x) > f(y)$.

ALGORITHM 3 (TESTING UNATENESS): On input n, ϵ and oracle access to $f : \{0,1\}^n \mapsto \{0,1\}$, do the following:

1. Uniformly select $m = O(n^{1.5}/\epsilon)$ strings in $\{0,1\}^n$, denoted $x^1, \ldots, x^m$, and m indices in $\{1, \ldots, n\}$, denoted $i^1, \ldots, i^m$.
2. For each selected x^j, obtain the values of $f(x^j)$ and $f(y^j)$, where y^j results from x^j by flipping the i^j-th bit.
3. If unateness is found to be violated then reject.

   Violation occurs, if among the string-pairs $\{x^j, y^j\}$, there exist two pairs and an index i, such that in both pairs the strings differ on the i^{th} bit, but in one pair the value of the function increases when the bit is flipped from 0 to 1, and in the other pair the value of the function increases when the bit is flipped from 1 to 0.

If no contradiction to unateness was found then accept.

Theorem 16 *Algorithm 3 is a testing algorithm for unateness. Furthermore, if the function is unate, then Algorithm 3 always accepts.*

The furthermore clause is obvious, and so we focus on analyzing the behavior of the algorithm on functions which are ϵ-far from unate.

6.1 Proof of Theorem 16

Our aim is to reduce the analysis of Algorithm 3 to Theorem 2. We shall use the following notation. For $\overline{\pi} = \pi_1 \cdots \pi_n$ (where each π_i is a permutation over $\{0,1\}$), let $\prec_{\overline{\pi}}$ denote the partial order on strings with respect to π. Namely, $x \prec_{\overline{\pi}} y$ if and only if for every index i, $x_i \leq_{\pi_i} y_i$. Let $\epsilon_{\mathrm{M},\overline{\pi}}(f)$ denote the minimum distance between f and any function g that is monotone with respect to π, and let $\delta_{\mathrm{M},\overline{\pi}}(f)$ denote the fraction of pairs x, y that differ on a single bit such that $x \prec_{\overline{\pi}} y$ but

$f(x) > f(y)$. For any f and π, consider the function $f_{\overline{\pi}}$ defined by $f_{\overline{\pi}}(x) = f(\pi_1(x_1) \cdots \pi_n(x_n))$. Then, $\epsilon_{\mathrm{M},\overline{\pi}}(f) = \epsilon_{\mathrm{M}}(f_\pi)$ and $\delta_{\mathrm{M},\overline{\pi}}(f) = \delta_{\mathrm{M}}(f_\pi)$. Hence, as a corollary to Theorem 2, we have

Corollary 17 *For any $f : \{0,1\}^n \mapsto \{0,1\}$, and for any sequence of permutations $\overline{\pi}$,*

$$\delta_{\mathrm{M},\overline{\pi}}(f) \;\geq\; \frac{\epsilon_{\mathrm{M},\overline{\pi}}(f)}{n} \,.$$

Our next step is to link $\delta_{\mathrm{M},\overline{\pi}}(f)$ to quantities which govern the behavior of Algorithm 3. For each $i \in \{1,\ldots,n\}$, and permutation π over $\{0,1\}$, let $\gamma_{i,\pi}(f)$ denote the fraction, among all pairs of strings that differ on a single bit, of the pairs x, y such that x and y differ only on the i^{th} bit, $x_i <_\pi y_i$, and $f(x) > f(y)$. In other words, $\gamma_{i,\pi}(f)$ is the fraction of pairs that can serve as evidence to f not being monotone with respect to any $\overline{\pi} = \pi_1, ..., \pi_n$ such that $\pi_i = \pi$. Note that in case f is monotone with respect to some $\overline{\pi}$, then for every i, $\gamma_{i,\pi_i}(f) = 0$. More generally, $\delta_{\mathrm{M},\overline{\pi}}(f) = \sum_{i=1}^n \gamma_{i,\pi_i}(f)$ holds for every $\overline{\pi}$ (since each edge contributing to $\delta_{\mathrm{M},\overline{\pi}}(f)$ contributes to exactly one $\gamma_{i,\pi_i}(f)$).

The distance of f from the set of unate functions, denoted $\epsilon_{\mathrm{U}}(f)$, is the minimum distance of f to any unate function; that is, $\epsilon_{\mathrm{U}}(f) = \min_\pi(\epsilon_{\mathrm{M},\overline{\pi}}(f))$. We next link the $\gamma_{i,\pi}(f)$'s to $\epsilon_{\mathrm{U}}(f)$.

Lemma 18 $\sum_{i=1}^n \min_\pi\{\gamma_{i,\pi}(f)\} \geq \frac{\epsilon_{\mathrm{U}}(f)}{n}$.

Proof: Let $\overline{\pi} = \pi_1 \ldots \pi_n$ be defined as follows: $\pi_i = \mathrm{argmin}_\pi\{\gamma_{i,\pi}(f)\}$. The key observation is

$$\delta_{\mathrm{M},\overline{\pi}}(f) \;=\; \sum_{i=1}^n \gamma_{i,\pi_i}(f) \;=\; \sum_{i=1}^n \min_\pi\{\gamma_{i,\pi}(f)\}$$

where the first equality holds for any π, and the second follows from the definition of this specific π. Using the above equality and invoking Corollary 17, we have

$$\sum_{i=1}^n \min_\pi\{\gamma_{i,\pi}(f)\} \;=\; \delta_{\mathrm{M},\overline{\pi}}(f) \;\geq\; \frac{\epsilon_{\mathrm{M},\overline{\pi}}(f)}{n} \;\geq\; \frac{\epsilon_{\mathrm{U}}(f)}{n} \,.$$

■

For each i, let $\Gamma_{i,\pi}(f)$ be the set of all pairs of strings x, y that differ only on the i^{th} bit, where $x_i <_\pi y_i$, and $f(x) > f(y)$. Lemma 18 gives us a lower bound on the sum $\sum_i \min_\pi\{|\Gamma_{i,\pi}|\}$. To prove Theorem 16, it suffices to show that if we uniformly select $\Omega(n^{1.5}/\epsilon_{\mathrm{U}}(f))$ pairs of strings that differ on a single bit, then with probability at least $2/3$, for some i we shall obtain both a pair belonging to $\Gamma_{i,\mathrm{id}}(f)$ and a pair belonging to $\Gamma_{i,\overline{\mathrm{id}}}(f)$ (where $\overline{\mathrm{id}}$ is the permutation $(1,0)$). The above claim is derived from the following technical lemma, which can be viewed as a generalization of the *Birthday Paradox*.

Lemma 19 *Let $\mathrm{S}_1, \ldots, \mathrm{S}_n, \mathrm{T}_1, \ldots, \mathrm{T}_n$ be disjoint subsets of belonging to a universe U. For each i, let use denote by p_i the probability that a uniformly selected element in U hits S_i, and by q_i the probability that it hits T_i. Let $\rho \stackrel{\text{def}}{=} \sum_i \min(p_i, q_i) > 0$. Then, for some constant c, if we uniformly select $2c \cdot \sqrt{n}/\rho$ elements in U, then with probability at least $2/3$, for some i we shall obtain at least one element in S_i and one in T_i.*

To derive the claim, let $S_i = \Gamma_{i,\mathrm{id}}(f)$ and $T_i = \Gamma_{i,\overline{\mathrm{id}}}(f)$. Then by Lemma 18, $\sum_i \min(p_i, q_i) \geq \epsilon_U(f)/n$. Now, using Lemma 19, the claim (and theorem) follow. So it remains to prove the last lemma.

Proof: Suppose, without loss of generality, that $p_i \leq q_i$, for every i. As a mental experiment, we partition the sample of elements into two parts of equal size, $c \cdot \sqrt{n}/\rho$. Let I be a random variable denoting the (set of) indices of sets S_i hit by the first part of the sample. We show below that with probability at least 5/6 over the choice of the first part of the sample,

$$\sum_{i \in I} p_i \quad \geq \quad \frac{\rho}{\sqrt{n}} \tag{13}$$

The lemma then follows since, conditioned on Eq. (13) holding, the probability that the second part of the sample does not include any elements from $\bigcup_{i \in I} T_i$, is at most

$$\left(1 - \sum_{i \in I} q_i\right)^{c \cdot \sqrt{n}/\rho} \quad \leq \quad \left(1 - \frac{\rho}{\sqrt{n}}\right)^{c \cdot \sqrt{n}/\rho} \quad < \quad \frac{1}{6}$$

where the last inequality holds for an appropriate choice of c.

To prove that Equation (13) holds with probability at least 5/6, we assume without loss of generality that the sets S_i are ordered according to size. Let $S_1, \ldots, S_k$ be all sets with probability weight at least $\rho/2n$ each (i.e., $p_1 \geq \ldots \geq p_k \geq \rho/2n$). Then, the total probability weight of all other sets $S_{k+1}, \ldots, S_n$ is less than $\rho/2$, and $\sum_{i=1}^{k} p_i \geq \rho/2$ follows. We first observe that by a (multiplicative) Chernoff bound (for an appropriate choice of c), with probability at least 11/12, the first part of the sample contains at least $4 \cdot \sqrt{n}$ elements in $\bar{S} \stackrel{\mathrm{def}}{=} \bigcup_{i=1}^{k} S_i$.

Let $I' \stackrel{\mathrm{def}}{=} I \cap \{1, \ldots, k\}$. That is, I' is a random variable denoting the indices of sets S_i, $i \in \{1, \ldots, k\}$ that are hit by the first part of the sample. By the above, with probability at least 11/12, we have $|I'| \geq 4 \cdot \sqrt{n}$. Thus, it remains to prove the following

Claim: Conditioned on $|I'| \geq 4 \cdot \sqrt{n}$, with probability at least 11/12, $\sum_{i \in I'} p_i \geq \frac{\rho}{\sqrt{n}}$.

Proof: Since conditioned on an element belonging to $\bar{S}$ it is uniformly distributed in that set, we may bound the probability of the above event, when selecting $4\sqrt{n}$ elements uniformly and independently in $\bar{S}$. Consider the choice of the j^{th} element from $\bar{S}$, and let I'_{j-1} denote the set of indices of sets hit by the the first $j-1$ elements selected in $\bar{S}$. Going for $j = 1, ..., 4\sqrt{n}$, we consider two cases. In case $\sum_{i \in I'_{j-1}} p_i \geq \frac{2 \cdot \sum_{i=1}^{k} p_i}{\sqrt{n}}$, we are done since $\sum_{i=1}^{k} p_i \geq \frac{\rho}{2}$. Otherwise (i.e., $\sum_{i \in I'_{j-1}}^{j-1} p_i < 2 \sum_{i=1}^{k} p_i/\sqrt{n} \leq 1/\sqrt{n}$), the probability that the j^{th} element belongs to $I' \setminus I'_{j-1}$ (i.e., it hits a set in $\{S_1, \ldots, S_k\}$ that was not yet hit), is at least $1 - 1/\sqrt{n}$, which is at least 2/3 for $n \geq 9$. Observe that if we toss $4\sqrt{n}$ coins with bias 2/3 towards heads then with probability at least 11/12 (provided n is big enough) we'll get at least $2\sqrt{n}$ heads. In our case, the heads correspond to getting a new element from $\bar{S}$, where each such element carries a p_i weight of at least $\rho/2n$. The claim follows. □

The lemma follows, as indicated above. ■

6.2 Testing Unateness over other Domain Alphabets and Ranges

For finite ordered sets Σ and Ξ, we say that a function $f : \Sigma^n \mapsto \Xi$ is *unate* if there exists a sequence $\overline{\pi} = \pi_1 \ldots \pi_n$, where each π_i is any one of the $|\Sigma|!$ permutation over Σ, for which the

following holds: For any two strings $x = x_1 \cdots x_n$, and $y = y_1 \cdots y_n$, if for every i we have $x_i \leq_{\pi_i} y_i$, then $f(x) \leq_\Xi f(y)$, where $<_\Xi$ is the order defined in Ξ, and $<_{\pi_i}$ denotes the total order induced by π_i on Σ (namely, $k \leq_{\pi_i} \ell$ if and only if $\pi_i(k) \leq \pi_i(\ell)$).

We show how to test unateness in case $\Xi = \{0, 1\}$, using a hybrid of Algorithm 2.3 and Algorithm 3: The algorithm selects uniformly pairs (x, y) so that x and y differ on a single coordiante, obtains the values $f(x)$ and $f(y)$, and constructs a partial order π_i on Σ for each i. That is, if the algorithm sees a pair (x, y) such that $x_i \neq y_i$ and $f(x) < f(y)$ then it records that in the i^{th} coordinate $x_i <_{\pi_i} y_i$. The algorithm rejects if for some i it encounters a contradiction to the partial order.

Defining $\gamma_{i,\pi}(f)$ analogously to the binary case, and using an argument as in Lemma 18 we obtain $\sum_i \min_\pi\{\gamma_{i,\pi}(f)\} = \Omega(\epsilon_{\mathrm{U}}(f)/n)^2$. Thus, there exists an i so that $\gamma_{i,\pi}(f) = \Omega(\epsilon_{\mathrm{U}}(f)^2/n^3)$ holds for all π's. Thus, if the basic step of the algorithm is repeated $O(n^3\epsilon_{\mathrm{U}}^{-2}\log(d!))$ times, then with probability at least 2/3 all possible $d!$ permuations are ruled out.

We believe that the algorithm works well also in case of general Ξ, maybe at the cost of a factor of $|\Xi|$. Unfortunately, the argument used in Subsection 5.2 does not extend.

7 Testing based on Random Examples

In this section we prove Theorems 5 and 6: establishing a lower bound on the sample complexity of such testers and a matching algorithm, respectively.

7.1 A Lower bound on sample complexity

Let M' be as defined in the proof of Item 2 in Proposition 4. Recall that M' has the property that there are no edges (in G_n) between pairs of vertices that both belong to M' but are not matched to each other (in M'). By possibly dropping edges from M' we can obtain a matching M'' so that $|\mathrm{M}''|$ is even and of size $2\epsilon \cdot 2^n$ (recall that $\epsilon = O(n^{-3/2})$). Using M'' we define two families of functions. A function in each of the two families is determined by a partition of M'' into two sets, A and B, of equal size.

1. A function f in the first family is defined as follows
   - For every $(v, u) \in A$, define $f(v) = 1$ and $f(u) = 0$.
   - For every $(v, u) \in B$, define $f(v) = 0$ and $f(u) = 1$.
   - For x with $w(x) \geq k$, for which f has not been defined, define $f(x) = 1$.
   - For x with $w(x) \leq k - 1$, for which f has not been defined, define $f(x) = 0$.
2. A function f in the second family is defined as follows
   - For every $(v, u) \in A$, define $f(v) = 1$ and $f(u) = 1$.
   - For every $(v, u) \in B$, define $f(v) = 0$ and $f(u) = 0$.
   - For x's on which f has not been defined, define $f(x)$ as in the first family.

It is easy to see that every function in the second family is monotone, whereas for every function f in the first family $\epsilon_{\mathrm{M}}(f) = |B|/2^n = \epsilon$. Theorem 5 is established by showing that an algorithm which obtains $o(\sqrt{|B|})$ random examples cannot distinguish a function uniformly selected in the

first family (which needs to be rejected with probability at least 2/3) from a function uniformly selected in the second family (which needs to be accepted with probability at least 2/3). That is, we show that the statistical distance between two such samples is too small.

Claim 20 *The statistical difference between the distributions induced by the following two random processes is bounded above by* $\binom{m}{2} \cdot \frac{|\mathrm{M}''|}{2^{2n}}$. *The* first process (resp., second process) *is define as follows*

- *Uniformly select a function* f *in the* first (resp., second) *family.*
- *Uniformly and independently select* m *strings,* $x^1, ..., x^m$, *in* $\{0,1\}^n$.
- *Output* $(x^1, f(x^1)), ..., (x^m, f(x^m))$.

Proof: The randomness in both processes amounts to the choice of B (uniform among all $(|\mathrm{M}''|/2)$-subsets of M'') and the uniform choice of the sequence of x^i's. The processes differ only in the labelings of the x^i's which are matched by M'', yet for u (resp., v) so that $(u,v) \in \mathrm{M}''$ the label of u (resp., v) is uniformly distributed in both processes. The statistical difference is due merely to the case in which for some i, j the pair (x^i, x^j) resides in M''. The probability of this event is bounded by $\binom{m}{2}$ times the probability that a specific pair (x^i, x^j) resides in M''. The latter probability equals $\frac{|\mathrm{M}''|}{2^n} \cdot 2^{-n}$. □

Conclusion. By the above claim, $m < 2^n/\sqrt{3|\mathrm{M}''|}$ implies that the statistical difference between these processes is less than $\frac{m^2}{2} \cdot \frac{|\mathrm{M}''|}{2^{2n}} < 1/6$ and thus an algorithm utilizing m queries will fail to work for the parameter $\epsilon = |B|/2^n$. Theorem 5 follows. ■

7.2 A matching algorithm

The algorithm consists of merely emulating Algorithm 1. That is, the algorithm is given $m \stackrel{\text{def}}{=} O(\sqrt{2^n/\epsilon})$ uniformly selected examples and tries to find a violating pair as in Step 3 of Algorithm 1. We assume $\epsilon > n^4 \cdot 2^{-n}$, or else the algorithm sets $m = O(2^n)$.

ALGORITHM 4: Input n, ϵ and $(x^1, f(x^1)), ..., (x^m, f(x^m))$.

1. Place all $(x^j, f(x^j))$'s on a heap arranged according to any ordering on $\{0,1\}^n$.
2. For $j = 1, ..., m$ and $i = 1, ..., n$, try to retrieve from the heap the value $y \stackrel{\text{def}}{=} x^j \oplus 0^{i-1}10^{n-i}$. If successful then consider the values $x^j, y, f(x^j), f(y)$ and in case they demonstrate that f is not monotone then reject.

If all iterations were completed without rejecting then accept.

ANALYSIS. Clearly, Algorithm 4 always accepts a monotone function, and can be implemented in time $\mathrm{poly}(n) \cdot m$. Using a Birthday Paradox argument, we show that for the above choice of $m = O(\sqrt{2^n/\epsilon})$, Algorithm 4 indeed rejects ϵ-far from monotone functions with high probability. We merely need to show the following.

Lemma 21 *There exists a constant* c *so that the following holds. If* $m \geq c \cdot \sqrt{2^n/\epsilon_{\mathrm{M}}(f)}$ *and if the* x^i*'s are uniformly and independently selected in* $\{0,1\}^n$ *then Algorithm 4 rejects the function* f *with probability at least* 2/3.

Proof: We consider the sets U and $\Delta(f)$, as defined in the proof of Theorem 2 (see Eq. (2) and Eq. (3), respectively). By Theorem 2, we have $|\Delta(f)| \geq \frac{\epsilon_{\mathrm{M}}(f)}{n} \cdot |\mathrm{U}| = \epsilon_{\mathrm{M}}(f) \cdot 2^{-(n+1)}$. Our goal is to lower bound the probability that the m-sample contains a pair in $\Delta(f)$. Towards this end, we partition the sample into two equal parts, denoted $x^{(1)}, ..., x^{(m/2)}$ and $y^{(1)}, ..., y^{(m/2)}$, For $i, j \in \{1, ..., m/2\}$, we define a 0-1 random variable $\zeta_{i,j}$ so that $\zeta_{i,j} = 1$ if $(x^{(i)}, y^{(j)}) \in \Delta(f)$ and $\zeta_{i,j} = 0$ otherwise. Clearly, the $\zeta_{i,j}$'s are identically distributed and we are interested in the probability that at least one of them equals 1 (equiv., their sum is positive). Note that the $\zeta_{i,j}$'s are dependent random variables, but they are almost pairwise independent as shown below. We first show that the expected value of their sum is at least $c^2/8$. Below, X and Y are independent random variables uniformly distributed over $\{0,1\}^n$.

$$\begin{aligned} \mu \stackrel{\mathrm{def}}{=} \mathrm{Exp}[\zeta_{i,j}] &= \mathrm{Pr}_{X,Y}[(X,Y) \in \Delta(f)] \\ &= \sum_{(x,y)\in\Delta(f)} \mathrm{Pr}_{X,Y}[X = x \ \& \ Y = y] \\ &= |\Delta(f)| \cdot \left(2^{-n}\right)^2 \ \geq \ \epsilon_{\mathrm{M}}(f) \cdot 2^{-(n+1)} \end{aligned} \tag{14}$$

Thus, $\mathrm{Exp}[\sum_{i,j} \zeta_{i,j}] \geq (m/2)^2 \cdot \epsilon_{\mathrm{M}}(f) 2^{-(n+1)} \geq c^2/8$, which for sufficiently large value of the constant c yields a big constant. It thus come at little suprise that the probability that $\sum_{i,j} \zeta_{i,j} = 0$ is very small. Details follows.

Let $\overline{\zeta}_{i,j} \stackrel{\mathrm{def}}{=} \zeta_{i,j} - \mu$. Using Chebishev's Inequality we have

$$\begin{aligned} \mathrm{Pr}[\sum_{i,j} \zeta_{i,j} = 0] &\leq \mathrm{Pr}\left[\left|\sum_{i,j} \overline{\zeta}_{i,j}\right| \geq (m/2)^2 \cdot \mu\right] \\ &\leq \frac{\sum_{i,j} \mathrm{Exp}[\overline{\zeta}^2_{i,j}]}{(m/2)^4 \cdot \mu^2} + 2 \cdot \frac{\sum_{i,j\neq k} \mathrm{Exp}[\overline{\zeta}_{i,j}\overline{\zeta}_{i,k}]}{(m/2)^4 \cdot \mu^2} \end{aligned}$$

using $\mathrm{Exp}[\overline{\zeta}_{i,j}\overline{\zeta}_{i',j'}] = \mathrm{Exp}[\overline{\zeta}_{i,j}] \cdot \mathrm{Exp}[\overline{\zeta}_{i',j'}] = 0$, for every 4-tuple satisfying $i \neq i'$ and $j \neq j'$. The first term above is bounded by

$$\frac{\sum_{i,j} \mathrm{Exp}[\zeta^2_{i,j}]}{(m/2)^4 \cdot \mu^2} = \frac{\sum_{i,j} \mathrm{Exp}[\zeta_{i,j}]}{(m/2)^4 \cdot \mu^2} = \frac{1}{(m/2)^2 \cdot \mu} \leq \frac{8}{c^2}$$

To bound the second term, we let X, Y and Z be independent random variables uniformly distributed over $\{0,1\}^n$, and use

$$\begin{aligned} \sum_{i,j\neq k} \mathrm{Exp}[\overline{\zeta}_{i,j}\overline{\zeta}_{i,k}] &\leq \sum_{i,j\neq k} \mathrm{Exp}[\zeta_{i,j}\zeta_{i,k}] \\ &= (m/2)^3 \cdot \mathrm{Pr}_{X,Y,Z}[(X,Y) \in \Delta(f) \ \& \ (X,Z) \in \Delta(f)] \\ &\leq (m/2)^3 \cdot |\{(x,y,z) : (x,y) \in \Delta(f) \ \& \ (x,z) \in \mathrm{U}\}| \cdot \left(2^{-n}\right)^3 \\ &\leq (m/2)^3 \cdot (|\Delta(f)| \cdot n) \cdot 2^{-3n} \\ &= (m/2)^3 \cdot \mu \cdot n \cdot 2^{-n} \end{aligned}$$

Combining all the above, we get

$$\begin{aligned} \mathrm{Pr}[\sum_{i,j} \zeta_{i,j} = 0] &\leq \frac{8}{c^2} + 2 \cdot \frac{(m/2)^3 \cdot \mu \cdot n \cdot 2^{-n}}{(m/2)^4 \mu^2} \\ &\leq \frac{8}{c^2} + 8 \cdot \frac{n \cdot 2^{-n}}{c\sqrt{2^n/\epsilon} \cdot \epsilon 2^{-n}} \end{aligned}$$

Using $\epsilon \geq n^2 2^{-n}$, the second term is bounded by $8/c$, and the lemma follows (for $c \geq 25$). $\square$

Acknowledgments

We would like to thank Dan Kleitmann and Michael Krivilevich for helpful discussions. In particular, Proposition 13 is due to Michael Krivilevich.
